Introduction

Measurement of burning velocities of gaseous fuel-air mixtures has been the subject of study for over five decades and a recent review by Konnov et al (2018) that has covered references on the subject. More than thousand researchers have been involved.

The above review and several other papers contain data comparisons for many fuel-air mixtures from various sources using a number of different techniques.

Also are contained predictions using premixed flame code (at least three codes) with reaction kinetics from different sources.

The dependences on initial temperature and pressure are extracted for the exponents on initial temperature and pressure.

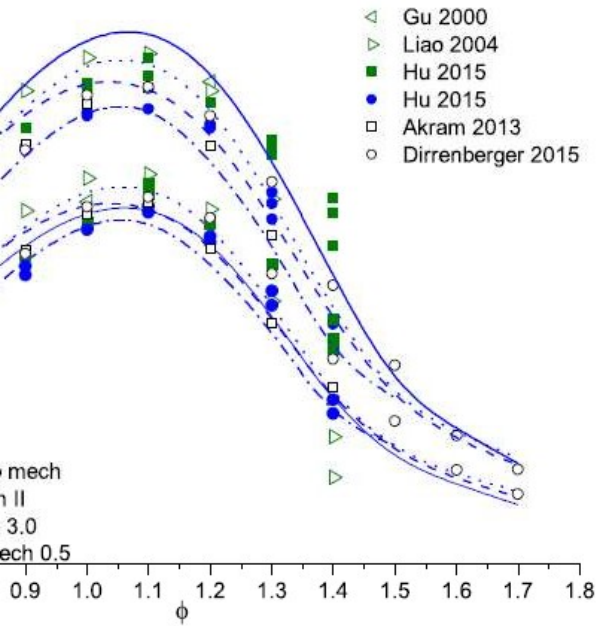

There are many correlations for each of the fuels including straight chain hydrocarbon

What appears clear from this paper is that the data show differences arising out of different researchers, different apparatus and schemes used for deduction for most of the differences being about $\pm 5\%$ for standard fuels and more close to $\pm 10\%$ for most other fuels.

While it is not obvious why the subject has received (or should receive) such an enhanced degree of interest on the part of researchers (and journals), this feature was what drew attention

...Motivation

From Konnov, et al, 2018

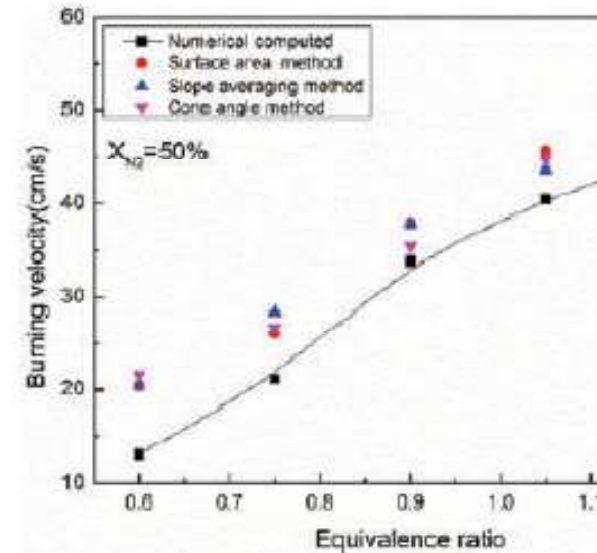

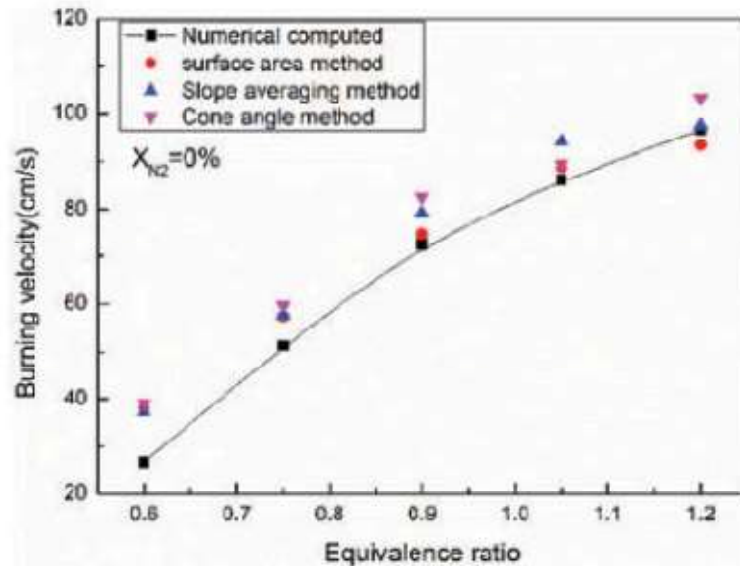

It can be noted, the scatter in the experimental data and the differences in the predictions by various methods (with different mechanisms and codes) is about 7%.

It is not easy to swear by theory (with complex chemistry and diffusion models) or experiment easily.

Instead of these, it was thought:

It might be useful if simpler correlations can be developed for a range of fuels together by examining the basic parameters for the variations with equivalence ratio (ϕ), and initial temperature (T_{ini})? The influence of pressure effects could also be simplified

From: Wu et al, 2018

CH ₄	H ₂	CO	CO ₂	N ₂
%	%	%	%	%
9.8	47.2	27	16	0
8.33	40.12	22.95	13.6	15
6.37	30.68	17.55	10.4	35
4.9	23.6	13.5	8	50

The calculations seem to under-predict significantly for nearly all compositions at lower equivalence ratios.

...the numerical simulation was conducted with GR-3 mechanism through using a premix code (PRO) to predict the burning velocity.

No other correlations? Curvefits?

Dong et al (2010) have set out a correlation as follows.

Basing on the experimental data, fitting curves of laminar flame speeds for H₂/air mixtures and NG/air mixtures are drawn in Figs. 5 and 6. The formulas for calculating laminar flame speed of H₂/air and NG/air mixtures are given in Eqs. (4) and (5):

$$S_{H_2} = -1.11019 + 4.65167\phi - 1.44347\phi^2 + 0.04868\phi^3, \quad (\phi = 0.8 - 2.1), R^2 = 0.993; \quad (4)$$

$$S_{NG} = -0.00075 + \frac{0.1352}{4 \times (\phi - 1.04072)^2 + 0.34623}, \quad (\phi = 0.8 - 2.1), R^2 = 0.983. \quad (5)$$

To calculate the laminar flame speed of H₂/NG/air mixtures, we define $(S_x - S_{NG}) / (S_{H_2} - S_{NG})$ as laminar flame speed increment. Here, S_x denotes the laminar flame speed at $x\%$ volumetric fraction of H₂. Figure 7 illustrates the increments of the laminar flame speed against volumetric fraction of H₂ for H₂/NG/air mixtures. The correlation between the increment of laminar flame speed and volumetric fraction of H₂ can be fitted as formula (6):

$$\frac{S_x - S_{NG}}{S_{H_2} - S_{NG}} = 0.00221 + 0.009 \exp\left(\frac{\phi}{21.30807}\right), \quad R^2 = 0.996. \quad (6)$$

Using Eqs. (4)–(6), the laminar flame speed at different volumetric fraction of H₂ and given equivalence ratio can be easily calculated.

The number of significant digits following the decimal point in the curve fits for a quantity that is about 5 to 10 % accurate is worrisome. - also too specific

Fig. 6 Fitting curve of laminar flame speed versus equivalence ratio for NG

Methodology for the simplified correlation - 1

burning rate depends on the adiabatic flame temperature ($T_{f, ad}$) and so, the crucial dependence of the burning rate variation with equivalence ratio (ϕ) is related to the variation of $T_{f, ad}$ with ϕ . This equilibrium thermochemistry dependent and not rate dependent. It is thought that if this could be factored in, simpler correlations of *greater generality* can be obtained. Finding a dimensionless dependence between $S_u/S_u(\phi = 1)$ and $T_f/T_f(\phi = 1)$ was thought first appropriate.

- The dependence is linear
- The constant slope is different for lean and rich cases
- It is inferred that the effect of flame temperature on burning rate in rich cases can be different from the lean as the role of flame temperature is more involved in rich mixtures.
- The fact that the behavior is linear, but with different slopes, is factored into the correlation.
- It is noted that the burning velocity peaks at a rich equivalence ratio and hence may bring in some inaccuracies in the simplified correlation.
- Such a behavior is taken valid for all hydrocarbons & ...

Methodology for the simplified correlation - 2

Temperature dependence is treated by plotting the burning velocity at $\phi = 1$ as a function of initial temperature

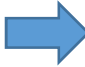

- This behavior is linear and can be described by a simple relationship.
- It is inferred that the relationship of S_u with $T_{f,c}$ reduces to this relationship after suitable linearization.
- The dependence on pressure has been presented in Konnov et al (2018) for a number of fuel-air mixtures (see for instance Fig. 40 of their paper).
- The variation set out here from different sources shows a complex variation over the equivalence ratio.

It is assumed that for the present purposes of getting an overall correlation, it is appropriate to choose a single pressure index for the pressure index.

A pressure index of - 0.3 is chosen for all straight-chain HCs after checking out the value for minimum error.

Therefore the correlation is set out as

$$Su \text{ (cm/s)} = 35.6 p^{-0.3} \left(\frac{T_f}{T_{f,\max}} - C \right) / (1-C) \left[\frac{(T_{ini} - 150)}{150} \right] \left[1 + 0.3 \left(\frac{M_f}{16-1} \right) \exp\{-0.8 * (\frac{M_f}{16-1})\} \right]$$

dependences on  p ϕ T_{ini} *Fuel*

p = pressure (atm), T_f and $T_{f,\max}$ are the adiabatic flame temperatures at any ϕ and at $\phi = 1$ (K), and constant = 0.65 for $\phi < 1$ and 0.8 for $\phi > 1$.

The stoichiometric burning velocity of CH_4 -air is taken as 35.6 cm/s. This is the basic burn rate of all straight hydrocarbons considered here (Acetylene excluded)

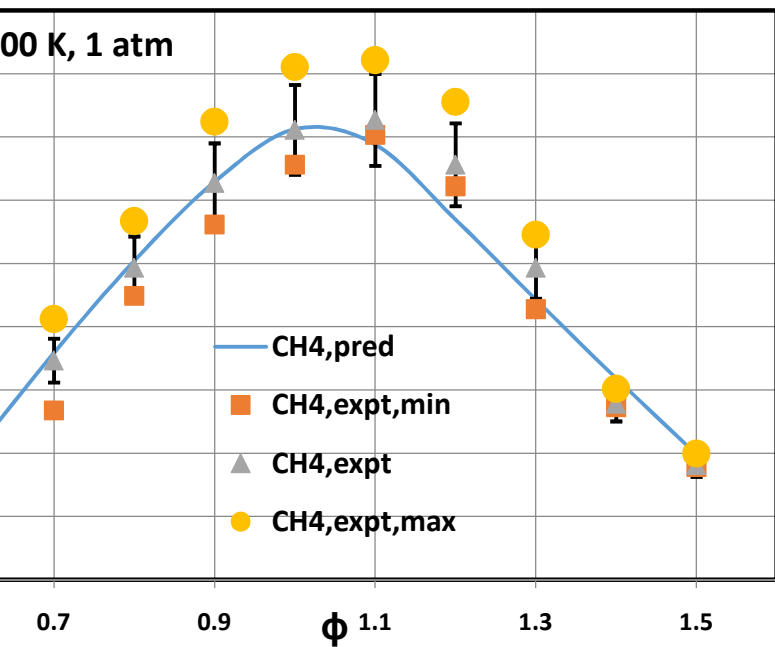

The dependence with respect to equivalence ratio is obtained through the dependence on the adiabatic flame temperature (that can easily be obtained online from NASA CEA code for any condition of relevance here).

On an examination of the data of peak burning velocities of higher hydrocarbons it is found that it increases from ethane, propane and butane to about 40 cm/s and settles down for octane at 35 cm/s. While once can argue that the differences are small, the term within the flower brackets accounts for this observation.

predictions depend on the above equation (No other constants introduced).

Predictions and comparisons Hydrocarbons & Alcohols

The basis of experimental data is: Konov et al, 2018

Hydrocarbons
at
P = 1 atm,
T_{ini} = 300 K

Comparisons
considered
satisfactory

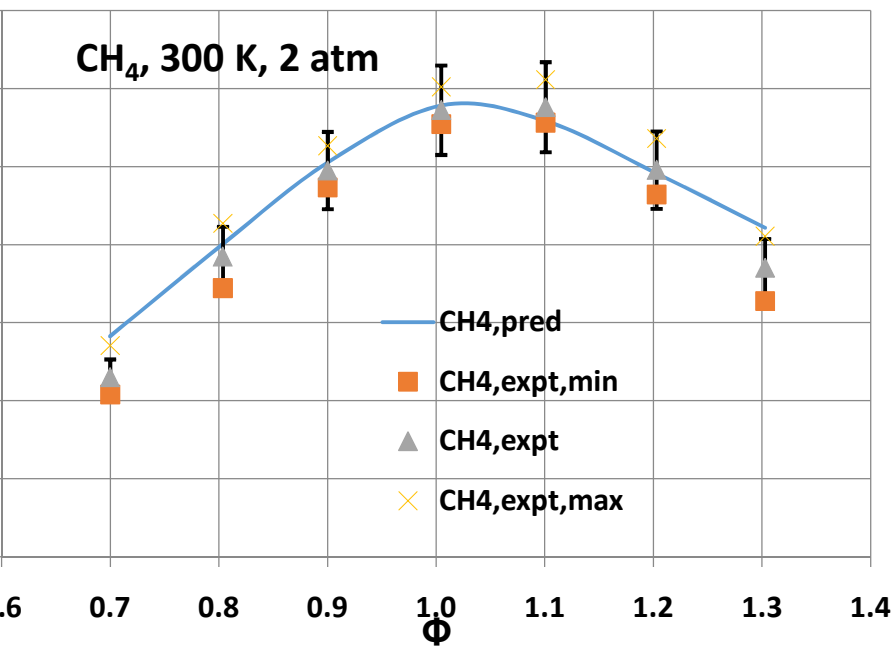

CH₄ at
 p = 1 atm
 but increasing T_{ini}

Comparisons
 considered
 satisfactory

Hydrocarbons
p = 2 atm,

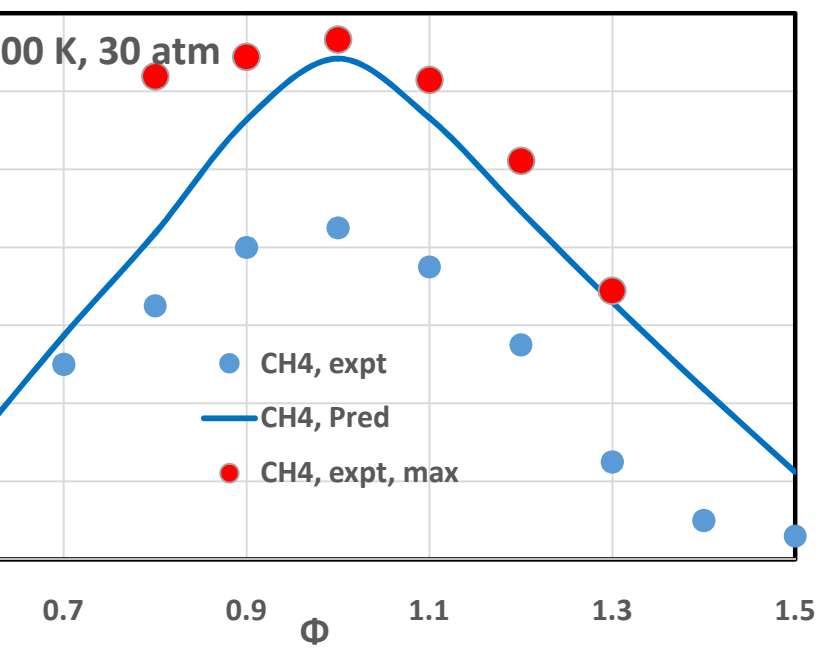

T_{ini} = 300 K
(& 373 K)

C₂H₆
predictions
on the rich
side are not
all that good

Is
experimental
data good?

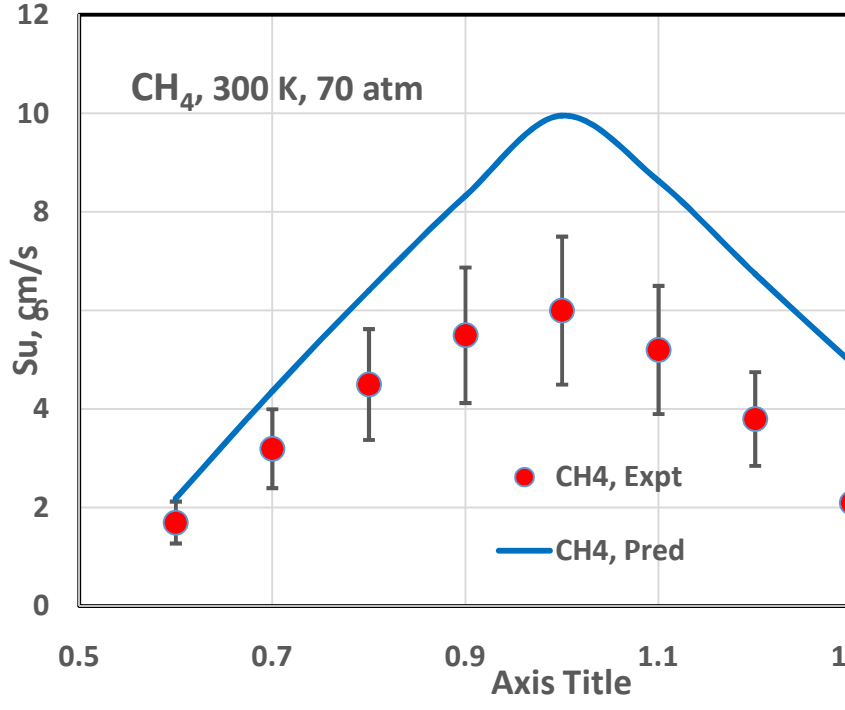

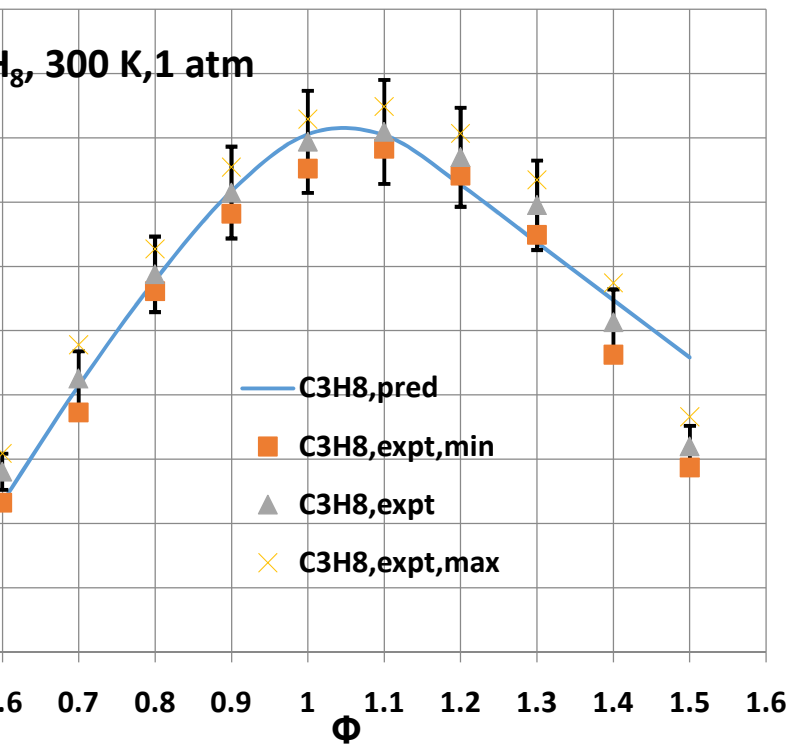

Methane
 $T_{ini} = 300 \text{ K}$
 $P = 2 \text{ to } 70 \text{ atm}$

Predictions at higher pressures do not seem good. But the data quality also does not seem good.

Perhaps these measurements have inherent difficulties

Propane at 300, 370 K,
1 atm
300 K, 2 and 5 atm

Comparisons
are satisfactory

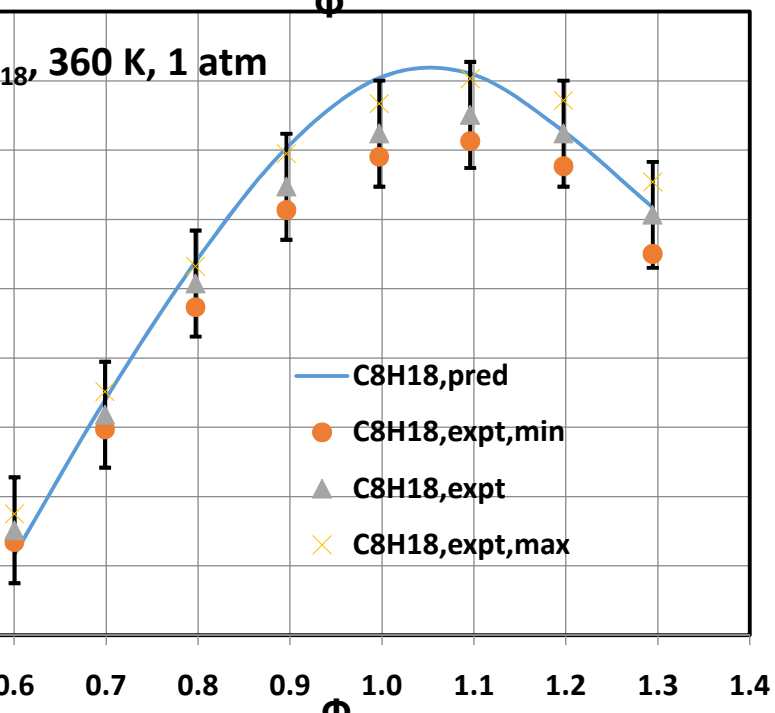

Butane and
Pentane
at 1 atm
different T_{ini}

Comparisons
are better
at lean conditions
Than under rich
conditions

Heptane and Octane at different conditions for which data are set out in Konnov et al

Comparisons reasonable

Ethyl Alcohol as extrapolated from Methane seems to behave very differently

CH₃OH even if treated as related to CH₄ in its combustion behavior with the oxygen atom integrated into the molecule allows higher reaction rates, no simple hypothesis can explain the complex behavior -

At 300 K, the burning velocity at the peak And under rich conditions are seriously under-predicted Also, at 373 K, lean flames are over-predicted

At 400 K, predictions seem reasonable!

No simple explanation seems possible for the observations.

Predictions and comparisons for Hydrogen and Syngas compositions

Experimental data are obtained from Li et al, 2016; Wu, et al, 2018; Kannov et al, 2018; these et al, 2019

clearly noted that the peak in burning velocity occurs at very rich equivalence ratios

means the approach chosen for hydrocarbons seeking relationship with adiabatic flame temperature variation alone will not work - because stronger diffusional effects -of H₂ come play.

unfortunately, the variation with equivalence ratio alone would be adequate, as is seen to W.....

Syngas compositions considered

Data: Konnov et al (2018).

H₂, 300 K, 0.5, 1, 2 atm

Syngas compositions

Approaches have been made for correlating the burning velocity which the more successful one is set out here.

Parameter, P1 is constructed such that it features of summation on mixture composition with burning velocities

$$+36.5f_{CH_4}+35f_{CO})$$

$$2 (P1 - 9) \text{ cm/s} \quad \text{for } P1 < 62 \quad \text{up to } \phi = 1.05$$

$$2.4 (P1 - 20) \text{ cm/s} \quad \text{for } P1 > 62$$

$$= 0.6) = 1.1 (P1-11)$$

$$\text{min}) / (Su, \text{max} - Su, \text{min}) = (\phi - 0.6) / (1.05 - 0.6)$$

$$P1 - 11) + (2 P1 - 13) (\phi - 0.6) \quad \text{for } P1 < 62$$

$$P1 - 11) + (2.5 P1 - 50) (\phi - 0.6) \quad \text{for } P1 > 62$$

are mole fractions of individual species in the mixture.

Equation does not distinguish between CO₂ and N₂ and is consistent with experimental data.

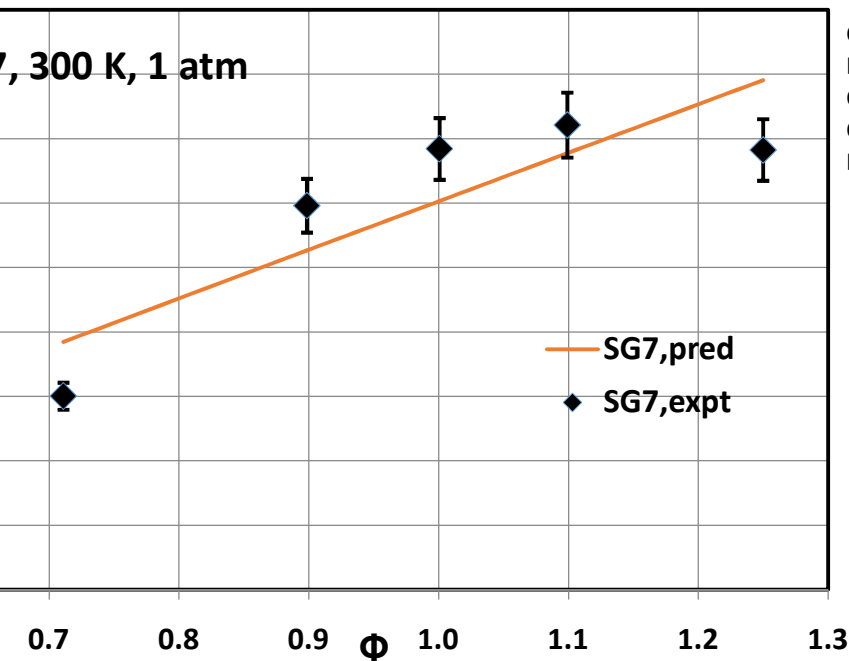

Comparisons appear good.

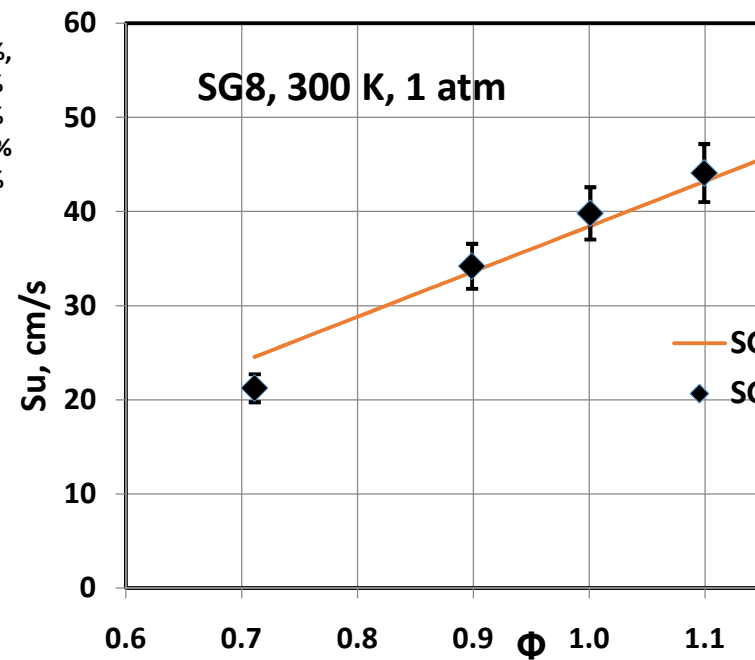

CO = 20 %,
H2 = 20 %
CH4 = 5 %
CO2 = 10%
N2 = 45 %

CO = 25 %,
H2 = 20 %
CH4 = 5 %
CO2 = 10%
N2 = 40 %

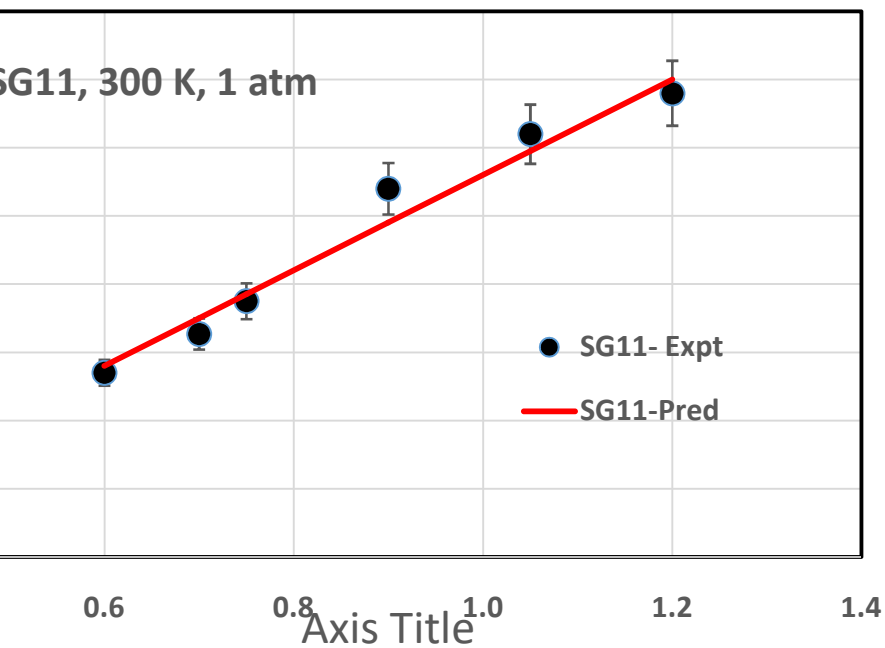

Comparisons are reasonably good

Comparisons are reasonable except for SG10.

It appears that computational results favor the simpler expectation!

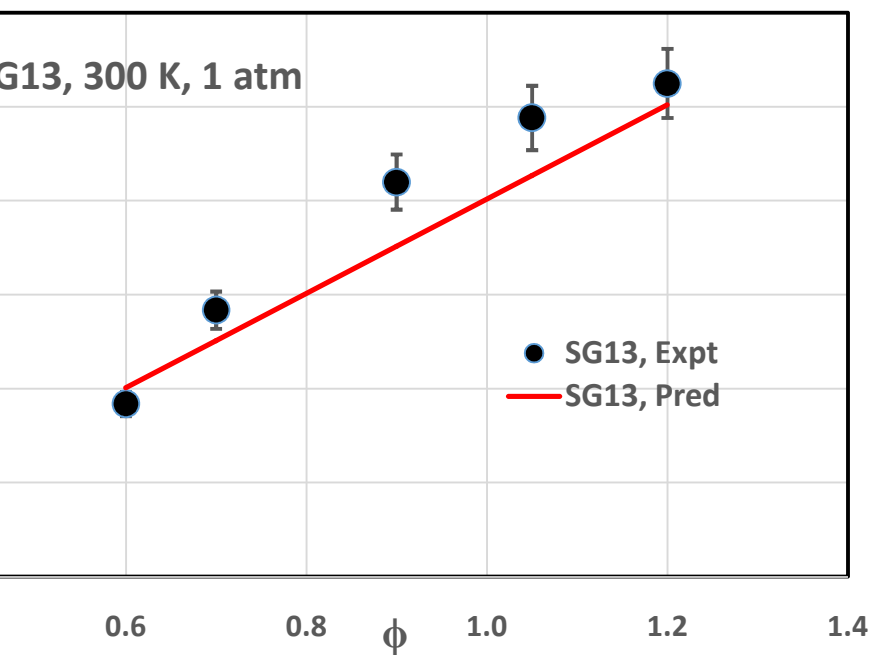

Observation:

The correlation seems to be able to distinguish between close but differently performing compositions.

Comparison
reasonable

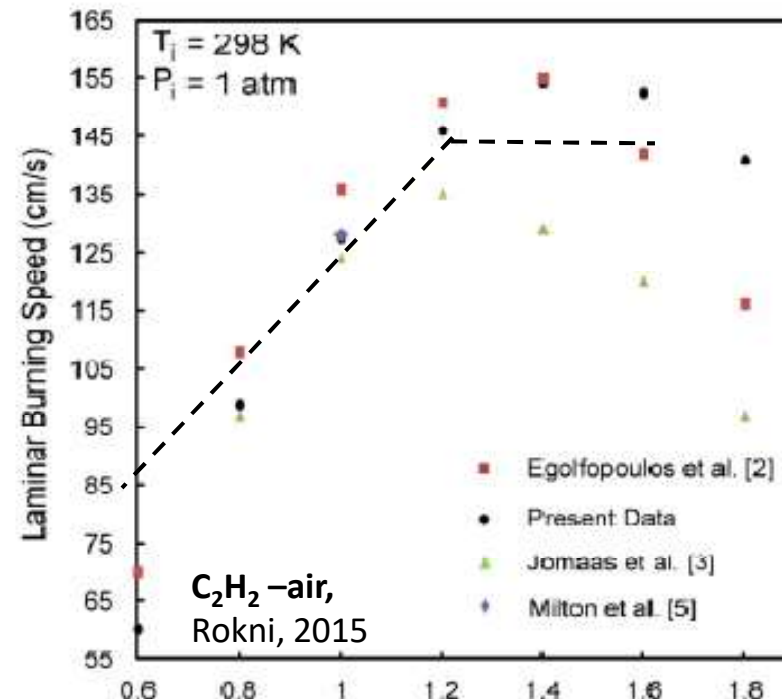

$$Su (C_2H_2) = 100 \phi + 25 \text{ cm/s}, \phi < 1.2$$

$$= 145 \text{ cm/s}, 1.8 > \phi > 1.2$$

This is just a curve fit since relating to simple hydrocarbons is tortuous, if not impossible. It is because the reactivity of acetylene arises from its triple bond

Overall performance of the correlations

Summary

premixed flame burning behavior of 45+ compositions of hydrocarbons + alcohols + hydrogen and syngas have been considered for study

simplified correlations the burning velocity of hydrocarbons + alcohols and hydrogen and syngas as the attempts have been attempted.

for hydrocarbons and alcohols for various initial temperatures and pressures (CH₃OH needs more studies)

$$S_u \text{ (cm/s)} = 35.6 p^{-0.3} (T_f/T_{f,max} - C)/(1-C) [(T_{ini}-150)/150] [1 + 0.3(M_f/16-1) \exp\{-0.8*(M_f/16-1)\}], T_f \text{ to be obtained from NASA CEC code}$$

for Hydrogen: $S_u \text{ (H}_2\text{, cm/s)} = 230 (\phi - 0.2) (1 - 1.9f_{N_2}) (T_{ini} - 150)/150 \text{ cm/s}$ for $0.2 < \phi < 1.4$, $= 276 (1 - 1.9f_{N_2}) (T_{ini} - 150)/150 \text{ cm/s}$ for $1.4 < \phi < 2.0$

for Syngas: $P1 = (100f_{H_2} + 36.5f_{CH_4} + 35f_{CO})$ $S_{u, max} = 2 (P1 - 9) \text{ cm/s}$ for $P1 < 62$ $= 2.4 (P1 - 20) \text{ cm/s}$ for $P1 > 62$, up to $\phi = 1.05$
 $S_{u, min} (\phi = 0.6) = 1.1 (P1 - 11)$

$$(S_u - S_{u, min}) / (S_{u, max} - S_{u, min}) = (\phi - 0.6) / (1.05 - 0.6); \text{ Therefore,}$$

$$S_u = 1.1 (P1 - 11) + (2 P1 - 13) (\phi - 0.6) \text{ for } P1 < 62$$

$$= 1.1 (P1 - 11) + (2.5 P1 - 50) (\phi - 0.6) \text{ for } P1 > 62, \text{ where } f_i \text{'s are mole fractions of individual species in the composition}$$

Several alternate, somewhat more involved correlations did not do as well as the above.

These experiments are beset with inaccuracies of measurement, calculations are beset with issues of kinetic schemes and other thermochemical details. The final outcome from these efforts do not point to any one correlation being superior at this stage (accuracies $\sim \pm 7$ to 10 %).

These data are intended for calculating for complex turbulent combusting premixed flows simpler correlations may as well do - except close to flammability limits where detailed chemistry matters

SG16	91.3	73.2

Comparisons of maximum Su are reasonable for 10 of the 16 cases considered here.

The comparisons are not good for some, but bad for SG14. High CO cases have an issue in this format.

$$Su(H_2) = 225(\phi - 0.2)(T_{ini}-150)/150, \text{ for } \phi < 1.4, 270(T_{ini}-150)/150 f_{H_2} \text{ for all } \phi > 1.4$$

$$Su(CH_4) = 36.5*(1.71\phi-0.71)(T_{ini}-150)/150 \text{ for } \phi < 1.0$$

$$Su(CO) = 60(\phi - 0.33)(T_{ini}-150)/150 f_{CO} \text{ for } \phi < 1.0$$

$$Su = [Su(H_2) f_{H_2} + Su(CH_4) f_{CH_4} + Su(CO) f_{CO}] (1-1.3 f_{CO_2}-0.45 f_{N_2}) \text{ for } \phi < 1$$

where f_i 's are mole fractions of individual species

The poor comparison of composition SG14 cannot be understood because any simple modification is inconsistent with some good comparisons like SG15.

For SG16, it appears that computational results compare better with simple predictions compared to experiments. CO has been known to burn very slowly without H₂O (moisture); $CO + OH \rightarrow CO_2 + H$ is supposedly the most dominant reaction.

CO problem remains to be resolved.
